Overview

- Brief intro to Ultra-Luminous X-ray sources
- Discovery of the ULX in ESO 243-49
 - Initial X-ray results
- Multi-wavelength follow-up
 - X-ray (Swift, Chandra)
 - UV (GALEX, Swift UVOT)
 - Near-infrared (Magellan)
 - Radio (ATCA)
- Concluding remarks

Introduction to ULXs

- Ultra-Luminous X-ray sources (ULXs):
 - extragalactic X-ray sources
 - located outside nucleus of host galaxy
 - bolometric luminosities $> 10^{39}$ erg/s
 - X-ray spectra consistent with accreting black holes
- If luminosity isotropic, implies black hole mass $\gg 10 M_{\text{sun}}$ or super-Eddington accretion
- Alternative: radiation could be beamed (geometric/relativistic)
- Hundreds of ULXs currently known, most with $L_x \sim 10^{39} - 10^{40}$ erg/s
- Handful of hyper-ULXs with $L_x \sim 10^{41}$ erg/s

ESO 243-49 HLX-1

- While hunting for soft-spectrum objects in 2XMM catalogue, identified 2XMM J011028.1-460421 (aka HLX-1)
- HLX-1 coincident with galaxy ESO 243-49, $\sim 8''$ from bulge
- Steep power law spectrum ($\Gamma = 3.4$) consistent with other ULXs
- At galaxy distance (95 Mpc) unabsorbed 0.2-10 keV $L_x \sim 10^{42}$ erg/s
- Derived $L_x \sim$ order of magnitude above previous record holder

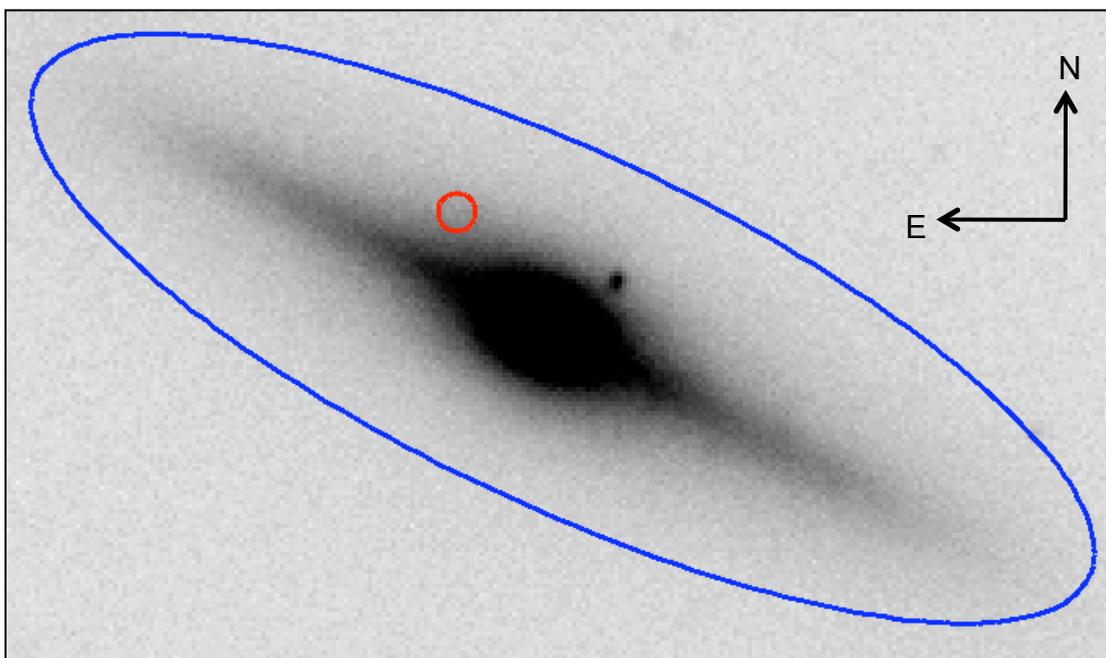

Initial X-ray Results

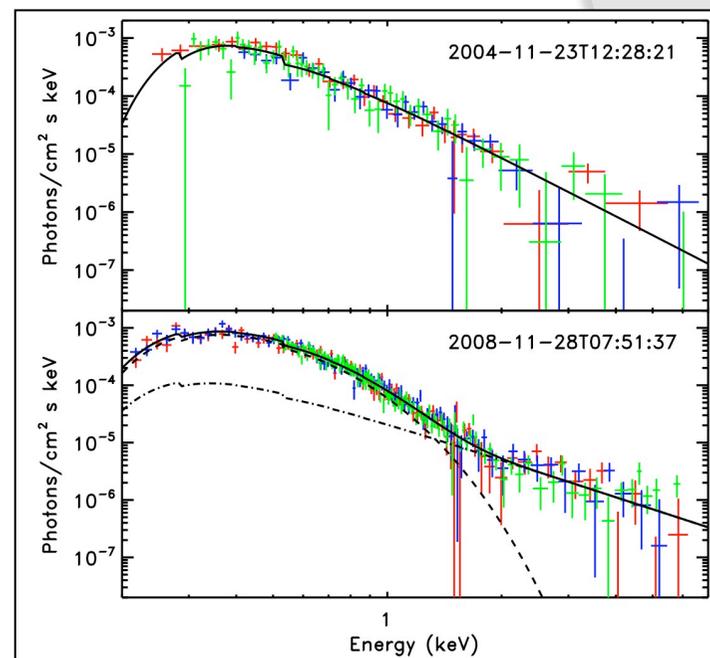

- Initially observed serendipitously in Nov 2004 by XMM-Newton
- ToO observation with Swift in Nov 2008 suggested spectrum had changed
- Follow-up DDT observation with XMM-Newton in Nov 2008 found L_x had dropped slightly ($\sim 6 \times 10^{41}$ erg/s)
- Second XMM spectrum inconsistent with first: new spectrum best fit by power law ($\Gamma = 2.2$) + disc black body ($kT = 0.18$ keV) model
- Disc black body contributes $\sim 76\%$ of 0.2 – 10 keV luminosity

$$P^2 = \frac{4a^3\pi^2}{G(M+m)}$$

ESO 243-49 HLX-1

VLT r-band image of ESO 243-49 with the position of HLX-1 marked (red circle)

Unfolded EPIC spectra showing steep power law (top) and power law + disc black body (bottom) fits

Farrell et al., 2009, Nature, 460, 73

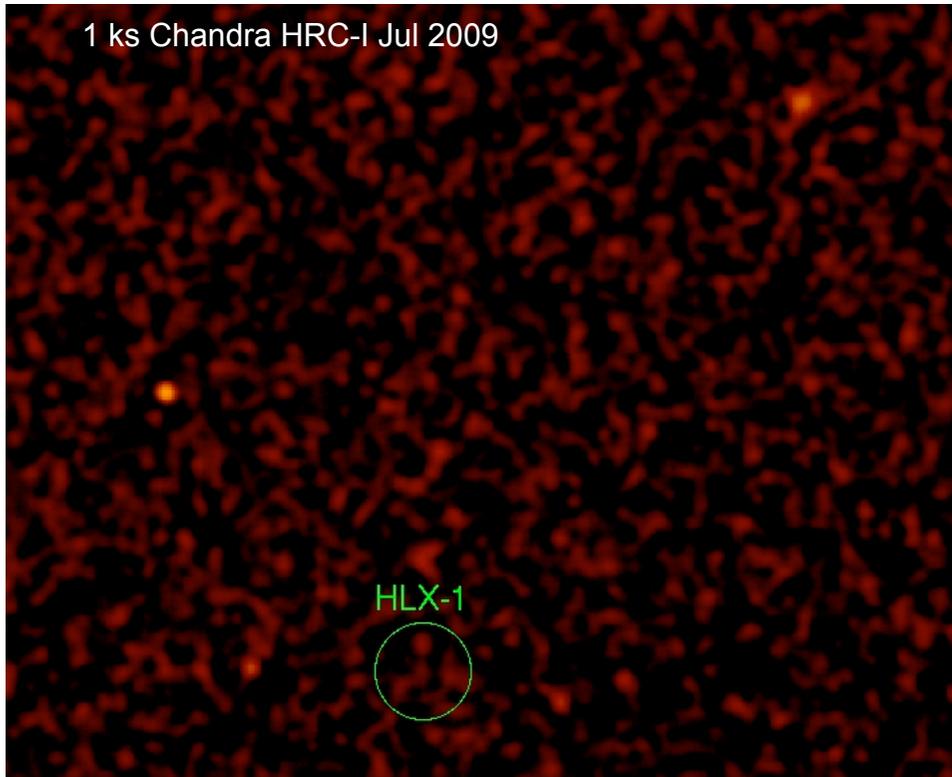

Follow-up: X-ray

- Obtained 1ks DDT observation with Chandra in Jul 2009
- HLX-1 not detected down to conservative upper limit of ~6 counts (expected ~35 counts)
- Monitoring campaign with Swift commenced in Aug 2009
 - HLX-1 detected clearly in ~19 ks with flat power law spectrum ($\Gamma = 2.2$) and $L_x \sim 6 \times 10^{40}$ erg/s
 - Additional observation 11 days later found flux had increased ($L_x \sim 1.1 \times 10^{42}$ erg/s) and spectrum purely thermal
- Obtained additional 10 ks DDT obs with Chandra in Aug 2009
- HLX-1 clearly detected (~600 counts)

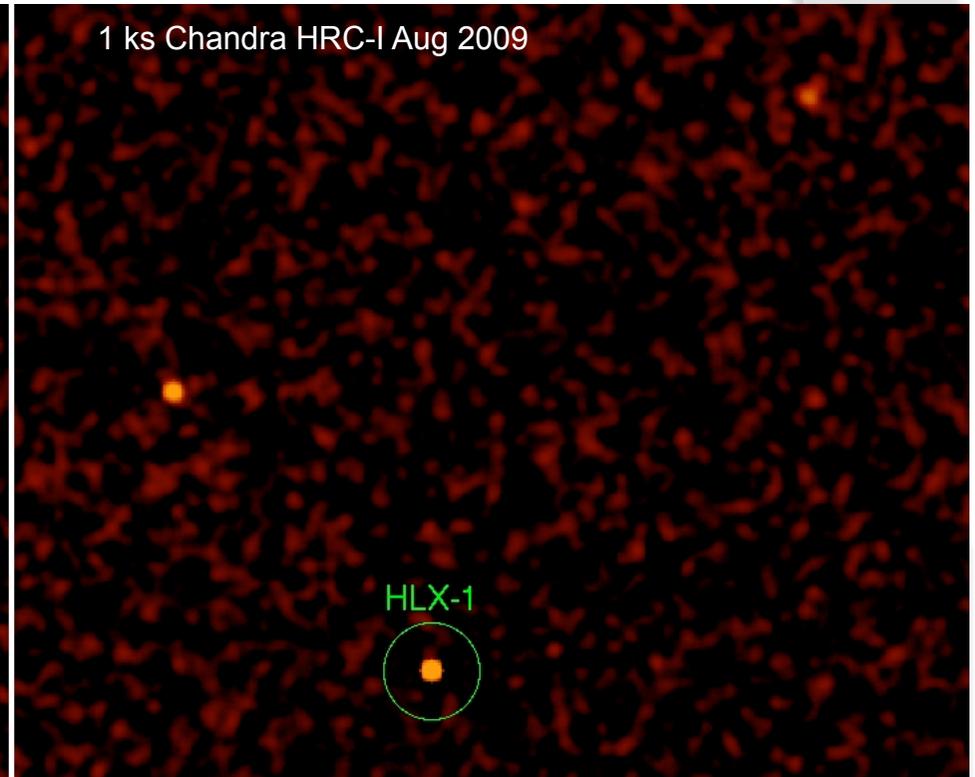

$$P^2 = \frac{4a^3\pi^2}{G(M+m)}$$

Follow-up: X-ray

1 ks Chandra HRC-I Jul 2009

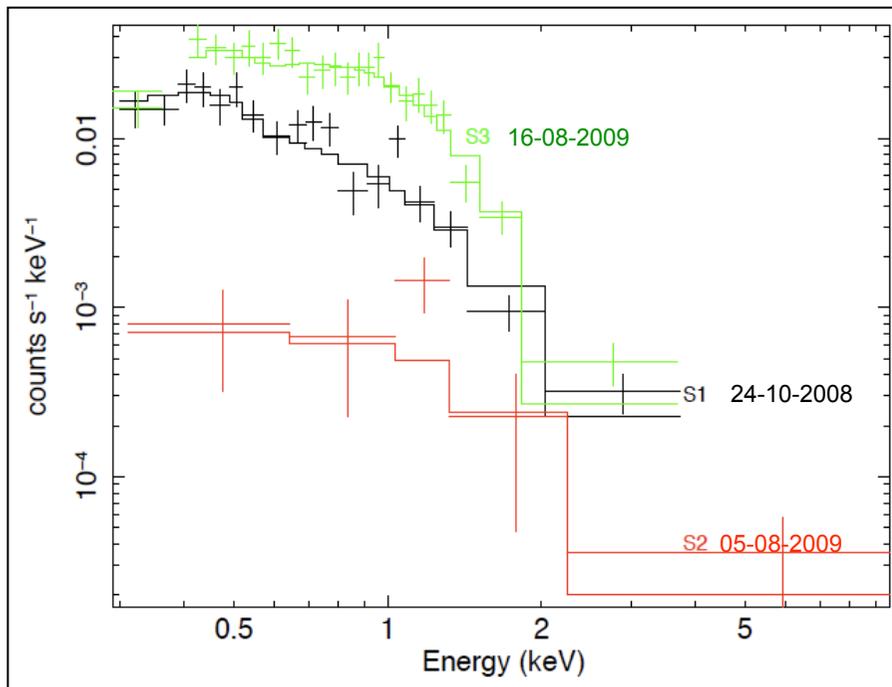

1 ks Chandra HRC-I Aug 2009

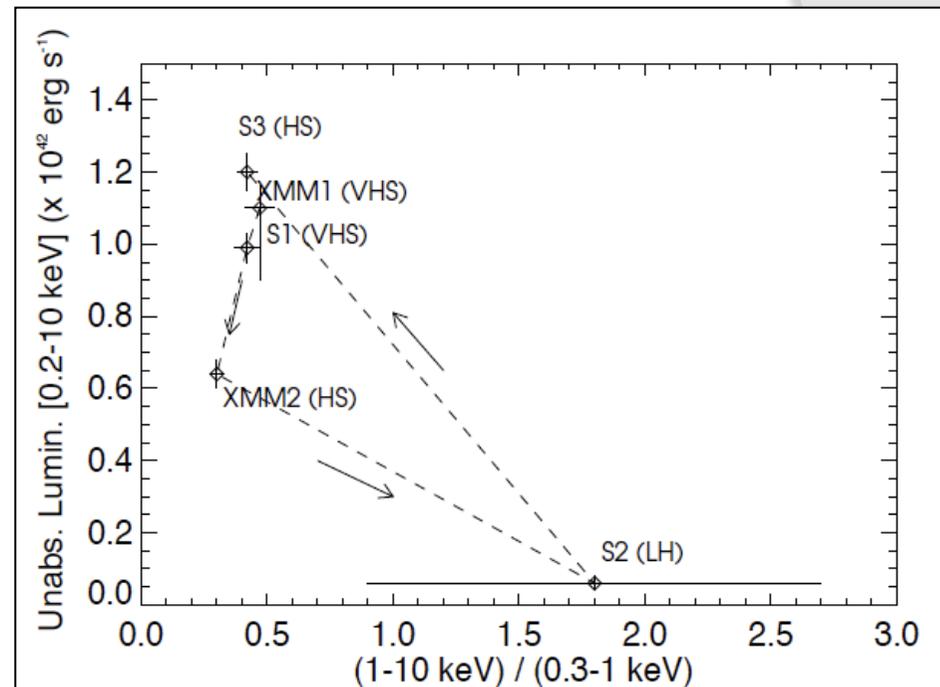

0.2 0.4 0.6 0.8

$$P^2 = \frac{4a^3\pi^2}{G(M+m)}$$

Follow-up: X-ray

Swift XRT spectra showing steep power law (black), flat power law (red) and disc black body (green) fits

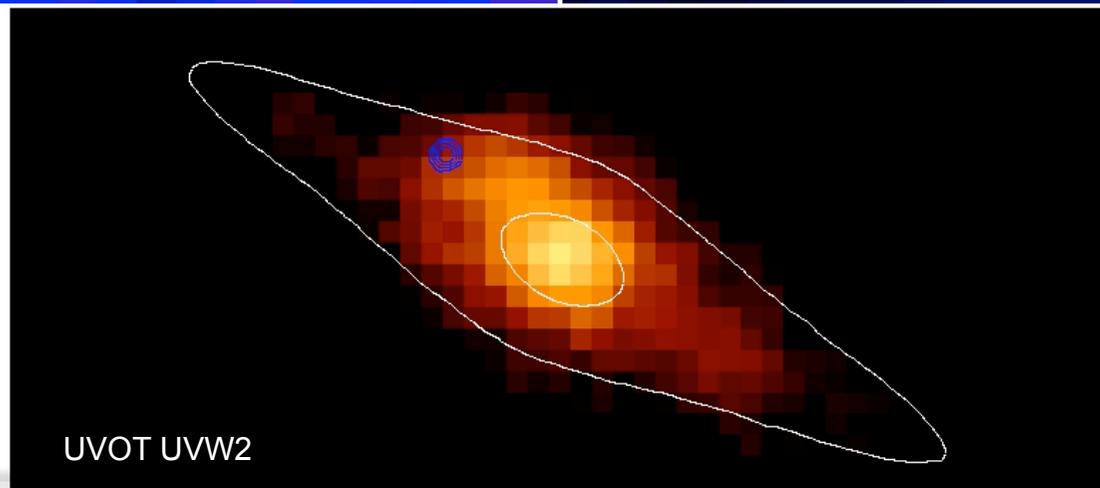

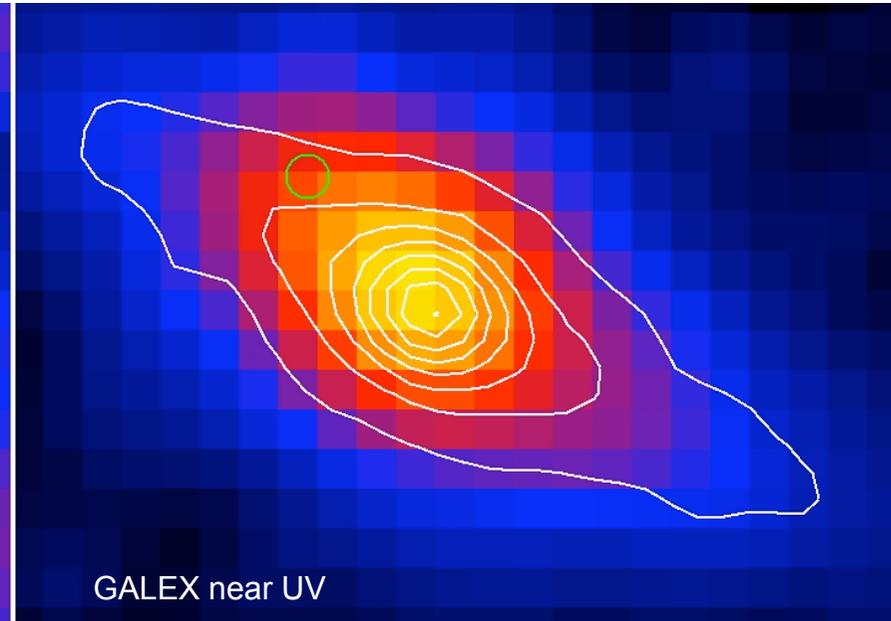

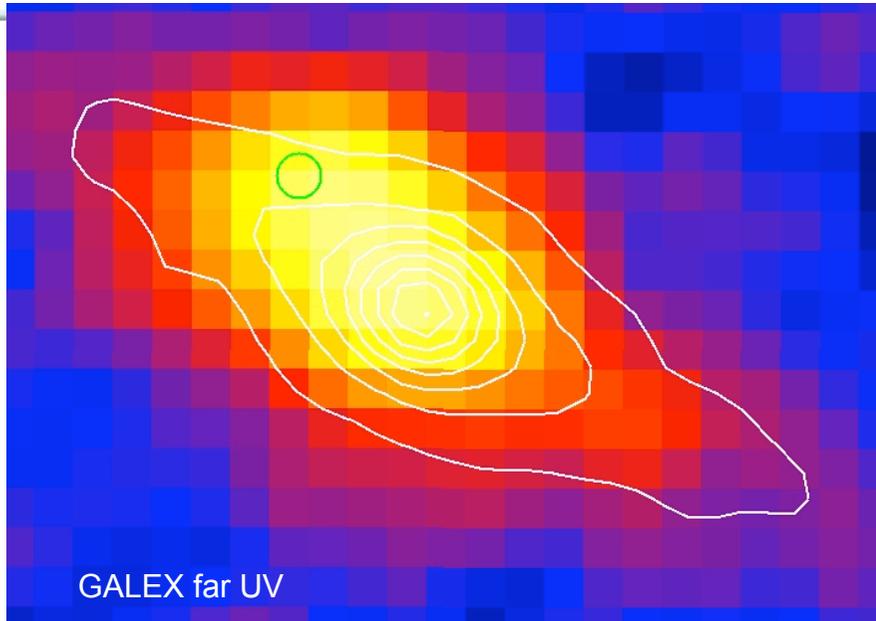

Hardness-Intensity diagram for XMM & Swift detections

Godet et al., 2009, ApJ, submitted

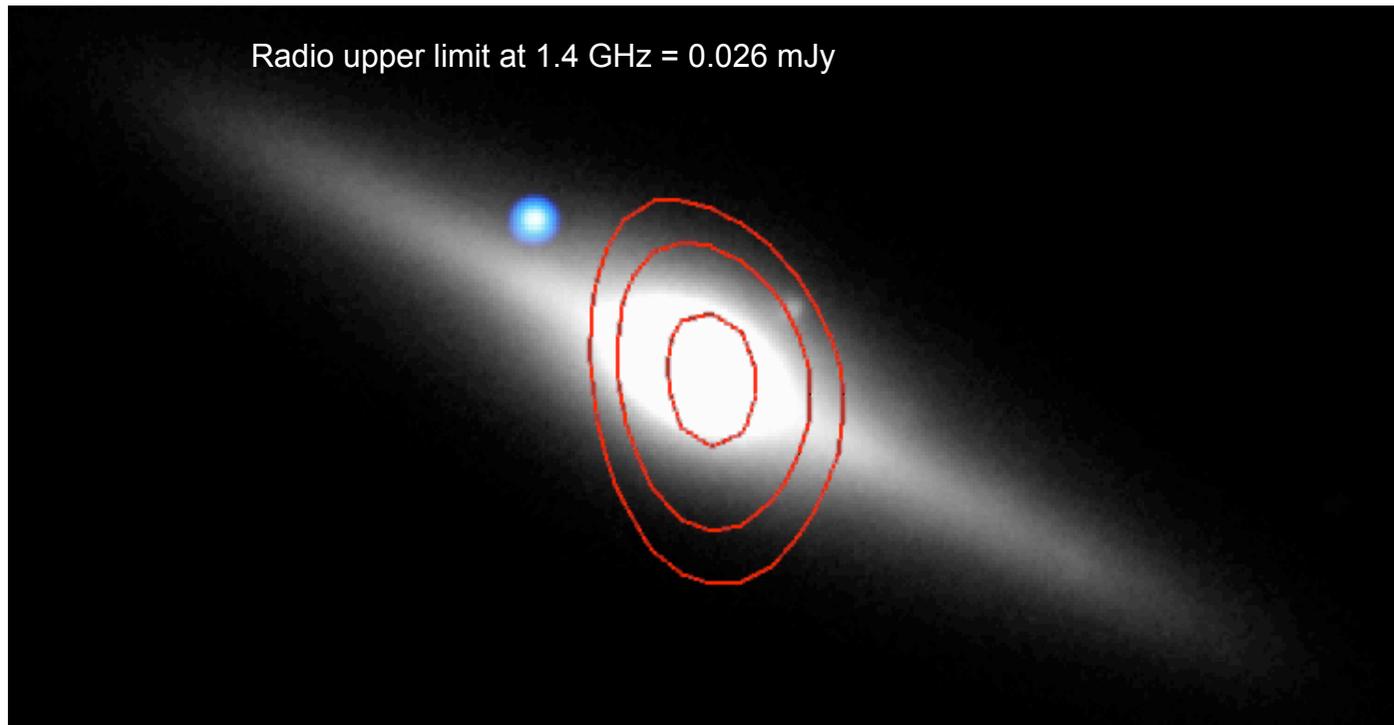

$$P^2 = \frac{4a^3\pi^2}{G(M+m)}$$

Follow-up: UV

Follow-up: NIR + Radio

$$P^2 = \frac{4a^3\pi^2}{G(M+m)}$$

Composite image showing the radio detection (red contours) overlaid on the J-band image of the galaxy (grey) from Magellan, and the X-ray data (blue) from Chandra

Webb et al., 2009, ApJ, in preparation

Conclusions

- Could it be a foreground object? Very unlikely as:
 - F_x/F_{opt} very high, ruling out most Galactic objects
 - X-ray spectra inconsistent with SNR, star, CV, neutron star XRB
 - Spectra + variability very consistent with Galactic black hole XRB
 - High state luminosity if its Galactic too low ($< 10^{34}$ erg/s)
- Could it be a background object? Also unlikely as:
 - Steep spectra inconsistent with most AGN
 - High F_x/F_{opt} seems inconsistent with narrow line Seyfert 1
 - Lack of radio counterpart rules out blazar
 - Timescale of spectral state changes inconsistent with super-massive black hole

Conclusions

- Variability definitively rules out multiple lower luminosity sources
- If emission isotropic and below Eddington limit, implies $> 5400 M_{\text{sun}}$
- Geometric beaming seems incompatible with spectral state transitions, as varying inner disc radius should effect beaming factor
- Eddington ratio of ~ 400 (assuming $20 M_{\text{sun}}$ black hole) should produce Lorentz factor of $\sim 5\text{--}10$, leading to relativistic beaming
- Lack of radio emission and steep spectra in high/very-high states argues against presence of jets
- Left with super-Eddington accretion: if maximum $L_x = 10 \times L_{\text{Ed}}$, implies **mass $> 500 M_{\text{sun}}$** (or possibly something even more exotic?)
